Punjab, India

Abstract Campus placement outcomes significantly influence both student career trajectories and institutional reputation. With increasing competition in the job market, educational institutions face challenges in identifying students who require additional academic or skill-based support prior to placement drives. This study presents a data-driven approach for predicting student placement outcomes using supervised machine learning classification techniques.

A structured student dataset containing academic performance, internship experience, aptitude scores, soft skills evaluation, extracurricular participation, and placement training history was analysed. After systematic data preprocessing, five classification algorithms—Logistic Regression, K-Nearest Neighbours (KNN), Decision Tree, Random Forest, and Naive Bayes—were implemented and evaluated. Model performance was assessed using accuracy, precision, recall, F1-score, and confusion matrix analysis. The results indicate that Logistic Regression delivers the most stable and interpretable performance among all evaluated models. The study demonstrates how machine learning can assist institutions in early identification of placement readiness and enable evidence-based academic interventions.

Introduction

Campus placements are a critical component of higher education outcomes, directly affecting students' professional opportunities and institutional credibility. Over the past decade, placement processes have evolved beyond academic performance alone, incorporating factors such as internships, aptitude assessments, certifications, and soft skills. As a result, traditional evaluation methods are no longer sufficient to predict placement success accurately.

With the growing availability of educational data, machine learning techniques provide a powerful framework for analysing complex relationships among multiple student attributes. Predictive models can uncover hidden patterns that help institutions proactively support students who may be at risk of not securing placements.

This study applies multiple machine learning classification algorithms to predict whether a student will be placed or not placed, based on a comprehensive set of academic and skill-related features.

1.1 Statement of the Problem

Despite structured academic curricula and placement training programs, many institutions lack analytical systems capable of predicting placement outcomes in advance. Placement decisions are often reactive rather than proactive, limiting the ability of colleges to intervene early. Without predictive insights, students who require additional training in aptitude,

communication, or technical skills may remain unidentified until placement drives begin.

There is a need for a data-driven predictive framework that evaluates student readiness for placements using historical academic and skill-based indicators.

1.2 Research Questions

This study addresses the following research questions:

1. Which academic and skill-based factors most strongly influence student placement outcomes?
2. How accurately can machine learning models predict placement status?
3. Which classification algorithm provides the best balance between accuracy and interpretability?
4. How do different models compare in terms of precision, recall, and error distribution?

1.3 Objectives of the Study

The objectives of this research are:

- To analyse student academic, technical, and behavioural attributes affecting placement success
- To preprocess and prepare educational data for machine learning analysis
- To implement and compare multiple supervised classification models
- To evaluate model performance using standard statistical metrics
- To identify the most effective model for placement prediction

1.4 Significance of the Study

This study is significant for multiple stakeholders. Educational institutions can use the predictive insights to design targeted placement training programs. Faculty and placement coordinators can identify students requiring additional academic or aptitude support. Students themselves benefit from early feedback on placement readiness. From an academic perspective, the study contributes to the application of machine learning in educational analytics and outcome prediction.

2. Literature Review

2.1 Educational Data Mining

Educational Data Mining (EDM) focuses on extracting meaningful patterns from student-related data to improve learning outcomes. Romero and Ventura (2010) highlighted the importance of predictive analytics in identifying at-risk students. Recent studies demonstrate that combining academic and non-academic variables improves prediction accuracy.

2.2 Factors Influencing Placement Outcomes

Several studies have identified CGPA, internships, aptitude scores, and soft skills as strong predictors of placement success. Kaur and Singh (2018) observed that students with higher industry exposure and communication skills showed improved placement performance compared to academically strong but less skilled peers.

2.3 Machine Learning in Placement Prediction

Logistic Regression, Decision Trees, and Naive Bayes are commonly used for placement prediction due to their interpretability. Ensemble models such as Random Forest improve accuracy but may reduce transparency. Comparative evaluation of multiple algorithms provides a balanced understanding of model effectiveness.

2.4 Research Gap

Although placement prediction has been explored, many studies focus on a single model or limited features. There is limited comparative analysis using multiple algorithms with standardized preprocessing and evaluation metrics. This study addresses that gap by implementing five models on the same dataset.

3. Methodology

3.1 Research Design

This study follows a quantitative and experimental research design aimed at predicting student placement outcomes using supervised machine learning techniques. The approach is based on analysing historical student data to identify relationships between academic performance, skill-based attributes, and final placement status. A classification-based modeling strategy was adopted, where the target variable represents a binary outcome indicating whether a student was placed or not placed. The design ensures objective evaluation of model performance through statistical metrics rather than subjective assessment.

3.2 Dataset Description

The dataset used in this research consists of individual student records collected from an academic placement database. Each record represents a student and includes attributes related to academic achievement, practical exposure, and behavioural competencies. Academic indicators include CGPA, secondary and higher secondary marks, while experiential attributes include internships completed, number of projects, and participation in workshops or certifications. Skill-based variables such as aptitude test scores and soft skills ratings

provide insight into employability readiness. In addition, extracurricular participation and placement training status are included to capture overall student engagement. The placement status serves as the dependent variable, indicating whether the student was successfully placed.

3.3 Tools and Technologies

The analytical workflow was implemented using the Python programming language due to its extensive support for data analysis and machine learning tasks. Data manipulation and preprocessing were carried out using Pandas and NumPy libraries. Visual exploration of the dataset was performed using Matplotlib and Seaborn to understand distributions, correlations, and patterns within the data. Machine learning model development and evaluation were conducted using the Scikit-learn library, which provides reliable implementations of classification algorithms and performance evaluation metrics.

3.4 Data Processing

Prior to model training, the dataset underwent several preprocessing steps to ensure data quality and consistency. Missing values in numerical attributes were handled by replacing them with the mean values of the respective columns, while missing categorical values were replaced using the mode to preserve dominant class representation. Duplicate records were identified and removed to prevent biased learning. Categorical variables such as extracurricular participation, placement training, and placement status were transformed into numerical form using label encoding. Furthermore, feature scaling was applied using standardization techniques to normalize the range of numerical features, ensuring fair contribution of all variables during model training.

3.5 Model Development

Following data preprocessing, the dataset was divided into training and testing subsets using an 80:20 split to enable unbiased model evaluation. Multiple supervised machine learning classification algorithms were implemented to predict student placement outcomes. Logistic Regression was used as a baseline linear classifier due to its interpretability and suitability for binary classification. K-Nearest Neighbours was employed to capture distance-based relationships among students. Decision Tree and Random Forest classifiers were applied to model non-linear relationships and feature interactions. Additionally, the Naive Bayes classifier was implemented as a probabilistic model based on conditional independence assumptions. Each model was trained using the training dataset and tested on unseen data to evaluate generalization performance.

3.6 Evaluation Metrics

The performance of each classification model was assessed using standard evaluation metrics commonly applied in binary classification problems. Accuracy was used to measure overall correctness of predictions, while precision and recall provided

insights into classification reliability and sensitivity, respectively. The F1-score was calculated to balance precision and recall, particularly in scenarios involving class imbalance. Confusion matrix analysis was used to examine true positives, true negatives, false positives, and false negatives, offering a detailed understanding of each model’s predictive behaviour.

4. Results & Findings

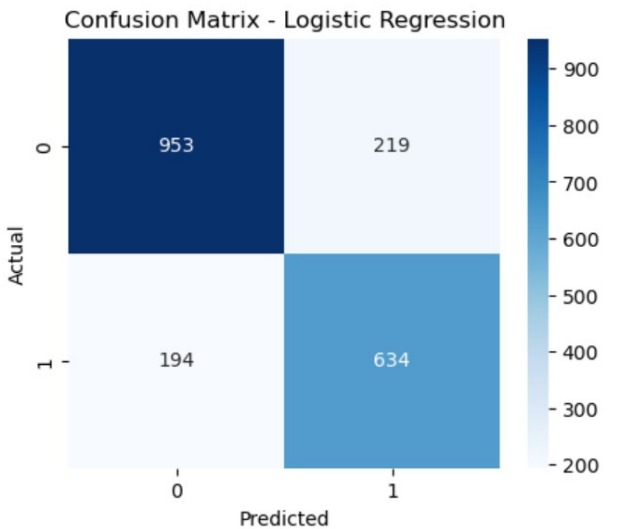

4.1 Model Performance Comparison

The Dashboard KPI Summary provides an overview of the After training and testing all five machine learning models, a comparative evaluation was conducted to understand their predictive performance. The results indicate noticeable variation in accuracy and classification behaviour across the implemented algorithms. Logistic Regression achieved the highest overall accuracy, demonstrating strong capability in distinguishing between placed and not placed students. Random Forest also performed competitively due to its ensemble nature, although its predictions showed slightly higher variability. K-Nearest Neighbours and Decision Tree classifiers produced moderate accuracy, while Naive Bayes exhibited relatively lower performance because of its simplifying assumptions.

Logistic Regression Results:				
Accuracy: 0.7935				
Confusion Matrix:				
[[953 219]				
[194 634]]				
Precision: 0.7433				
Recall: 0.7657				
F1 Score: 0.7543				
Classification Report:				
	precision	recall	f1-score	support
0	0.83	0.81	0.82	1172
1	0.74	0.77	0.75	828
accuracy			0.79	2000
macro avg	0.79	0.79	0.79	2000
weighted avg	0.79	0.79	0.79	2000
Naive Bayes Results:				
Accuracy: 0.7935				
Confusion Matrix:				
[[925 247]				
[166 662]]				
Precision: 0.7283				
Recall: 0.7995				
F1 Score: 0.7622				
Classification Report:

weighted avg	0.80	0.79	0.79	2000

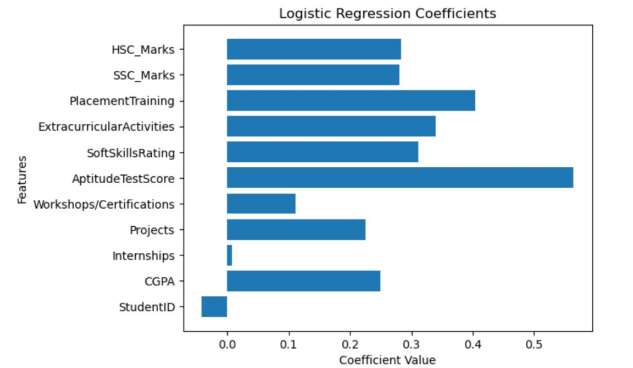

4.2 Confusion Matrix Analysis

Confusion matrix analysis was carried out to examine the distribution of correct and incorrect predictions. Logistic Regression generated fewer false positives and false negatives compared to the other models, indicating balanced classification behaviour. This is particularly important in placement prediction, where incorrect classification of a student’s placement readiness can result in missed opportunities or unnecessary intervention. In contrast, Decision Tree and KNN models showed higher misclassification rates, suggesting sensitivity to data variations and overlapping class boundaries.

4.3 Feature Influence on Placement Outcome

To understand the factors influencing placement outcomes, feature coefficient analysis from the Logistic Regression model was examined. The analysis revealed that CGPA and aptitude test score had the strongest positive influence on placement probability. Participation in placement training and completion of internships also contributed significantly to positive outcomes. These results suggest that both academic consistency and employability-oriented preparation are critical for placement success.

5. Discussion

5.1 Interpretation of Findings

The findings confirm that student placement outcomes depend on multiple interrelated factors rather than academic performance alone. Students who combined strong academic records with aptitude skills, internships, and training programs demonstrated higher placement success. This highlights the importance of holistic student development and structured employability initiatives within academic institutions.

5.2 Comparison with Existing Studies

The results align with previous research in educational data mining, which emphasizes the importance of internships and skill development in placement success. Studies conducted by Sharma et al. and Kaur et al. similarly identified aptitude assessments and training programs as significant predictors of employability. The consistent performance of Logistic Regression across studies reinforces its suitability for educational outcome prediction due to its transparency and reliability.

5.3 Practical Implications

From an institutional perspective, the predictive framework developed in this study can be used to identify students who may require additional support at an early stage. Placement cells can design targeted aptitude training, internship guidance, and communication skill programs based on predictive insights. Such proactive measures can improve overall placement rates and reduce last-minute placement failures.

6. Conclusion

6.1 Summary of the Study

This research explored the application of machine learning techniques to predict student placement outcomes using academic, skill-based, and experiential attributes. Five supervised classification models were implemented and evaluated using standard performance metrics. Among them, Logistic Regression emerged as the most effective and interpretable model for predicting placement success.

6.2 Limitations and Future Scope

Despite its contributions, the study has certain limitations, including a relatively small dataset and restriction to a single institutional context. Future research may involve larger datasets across multiple institutions, inclusion of behavioural and psychological attributes, and the application of advanced ensemble or deep learning models. Integrating predictive analytics into real-time academic systems can further enhance student placement preparedness.
